Abstract. The response of the ring current region is compared for periods of storm and substorm activity, with an attempt to isolate the contributions of both processes. We investigate CRRES particle data in an overview format that allows the display of long-term variations of the outer radiation belt. We compare the evolution of the ring current population to indicators of storm (*Dst*) and substorm (*AE*) activity and examine compositional changes. Substorm activity leads to the intensification of the ring current at higher L ($L \sim 6$) and lower ring current energies compared to storms ($L \sim 4$). The O^+/H^+ ratio during substorms remains low, near 10%, but is much enhanced during storms (can exceed 100%). We conclude that repeated substorms with an $AE \sim 900$ nT lead to a ΔDst of ~ 30 nT, but do *not* contribute to *Dst* during storm main phase as substorm injections do not form a symmetric ring current during such disturbed times.

Introduction

The role of storms in the filling of the radiation belts and the ring current region has been well established [Lui *et al.*, 1987; Lyons and Williams, 1975]. The exact role that substorms can play in this scenario is still a matter of debate.

Substorms generally occur more frequently during the active phase of a storm, and can substantially modify the recovery behavior of storms Gonzalez *et al.* [1994], leading to a much slower recovery in the presence of multiple substorms. It has been difficult up to now to differentiate between storm only changes in the ring current (*Dst*) and the substorm contribution to these changes. McPherron [1997] in his statistical study of the role of substorms during magnetic storms concludes that the effect of particles injected

during substorm expansion phase is undetectable in the pressure corrected *Dst* index. On the other hand, Gonzalez *et al.* [1994] shows clearly how continuous substorm activity in the recovery phase can keep *Dst* depressed for days after a storm. Simulation work with the Magnetospheric Specification and Forecast Model Wolf *et al.* [1997] has addressed this question as well. They concluded that potential convection electric fields during the storm main phase play a far more important role in ring current injection than do substorm-associated induction fields. They also show that when the magnetosphere is highly compressed > 50 keV ions are shadowed by the magnetosphere. Substorm injections during such times are thus unlikely to yield symmetric ring current contributions and do not have long lifetimes.

To compliment the statistical and modeling work mentioned above We investigate here particle populations as measured in the inner magnetosphere. We extend here on the work of Korth and Friedel [1997] which investigated storm-time dynamics to include substorm-only times as well. We present electron and ion composition measurements over the whole outer region for two separate events - one a classic storm and one a series of substorms which in their *Dst* signatures would be classed as a "small storm" [Gonzalez *et al.*, 1994]. By separating out the two classes of events, which normally occur as a superposition of one another, we can determine their individual responses. We further include ion composition measurements, in order to determine the contribution of individual species to the ring current density.

Mission and Instrumentation

This study uses particle measurements on the Combined Release and Radiation Effects Satellite (CRRES), which had an elliptical, 18.1° inclination orbit, and covered the regions up to $L = 8$, giving an L -

profile twice an orbit, at magnetic latitudes mostly within 20° of the magnetic equator.

On CRRES, the Medium Electrons B spectrometer (MEB, Korth et al. [1992]) covers electrons from 21 keV to 285 keV and total ions (no composition) from 37 keV to 3.2 MeV. The Medium Electrons A spectrometer (MEA, Vampola et al. [1992]) covers electrons from 143 keV to 1.58 MeV. The Magnetospheric Ion Composition Spectrometer (MICS, Wilken et al. [1992]) measures the mass, energy, and the charge of particles with energies of 1–430 keV/charge.

Observations

The data presented in this paper are L -sorted plots versus time of the type used by Friedel and Korth [1995]; Korth and Friedel [1997]. For each half-orbit (4:55 hours) the data binned in $0.2 L$ which is one vertical stripe in the plots. L -values are from the Olson-Pfizer 1977 quiet model. Magnetic latitude dependence is corrected in the MEB data set [Friedel and Korth, 1995].

In Plates 1,2 the panels are numbered in red from the top, $1 \rightarrow 11$.

Panels 10, 11 show Dst as a measure of the ring current, and the AE as a measure of substorm activity.

Panels 1–9 show the particle populations inside the magnetosphere:

Panels 5–7 displays three ion flux channels with peak energies of 45.5, 61.5, and 99 keV and panels 8 and 9 two electron flux channels with peak energies of 26 and 212.5 keV. This energy range represents the peak of the ring current density (30–300 keV).

Panel 4 displays the energy density of all ions (mostly H^+) in the ring current, as determined from the MEB instrument.

Panels 1 to 3 show the energy density of heavier ions (O^+ , He^+ , He^{++}).

Classic Storm (9/10 October 1990)

An isolated magnetic storm ($Dst = -133$ nT) is shown in Plate 1 over a time period of 17 days. The (B_z , ΔT) trigger of -8.7 nT for about 10 hours indicates an intense storm [Gonzalez et al., 1994]. Northward turning of B_z (solid line) initiates the recovery phase.

Comparing Planels 10 and 11 shows that the normal exponential recovery of the storm in Dst is delayed at the time of onset of a series of substorms. The

particles injected by these substorms are not clearly seen except at high L in Panel 9.

We identify the maximum of the outer radiation belt in this energy range (panel 4) as being roughly the "position" of the ring current. The prestorm maximum is between $L=3.5$ – 5.5 for these energies. With the beginning of the recovery phase the ring current intensifies (electrons and ions) and the maximum is displaced earthward by about half an Earth radius. The slot region narrows and widens again later.

He^{++} (alpha particles) have direct access during the storm and decay due to charge exchange to He^+ and diffuse radially inward during the storm recovery phase, and thus reach their maximum intensity ~ 5 hours after recovery onset. The maximum energy density of He^{++} is between $L = 4.5 \rightarrow 6$, further out than the main ring current density. Due to the low fluxes during this event, and the delayed appearance these ions do not contribute to the main phase of the storm but may contribute to the delay in recovery. However, the He^{++} flux observed depends very much on the solar wind composition. For the storms investigated so far the energy density ratio of He^{++}/H^+ can vary between 2% and 30%.

O^+ is of ionospheric source and together with He^+ intensifies at storm recovery, and constitutes part of the ring current between $L = 3.5 \rightarrow 5.5$, closer in than the He^{++} contribution. The energy density ratio of He^+/H^+ and O^+/H^+ is 0.02 and 0.22, respectively. The ratio increases normally with increasing Dst and for O^+/H^+ in particular can reach 50% [Daglis, 1997]. O^+ can thus be a major ring current constituent during storms. He^+ is low as it depends on He^{++} . The contribution of the heavy ions in the ring current decaying on a shorter time scale (a few days) compared within the main ring current. The intensities in Panel 1 to 3 drop off quickly after 3 days, at which time Dst also shows an accelerated recovery.

Substorms Series (6–16 February 1991)

Plate 2 shows a ten days period during which we observe continuous substorm activity. A solid line indicates the onset of this activity and the beginning of a decrease in Dst to a minimum of -34 nT. Each major peak in AE is associated with a decrease in Dst . During this time the B_z -component of the IMF (not shown) exhibits small-amplitude fluctuations with negative excursions between 1.5 and 4.5 nT for durations of up to four hours.

The AE index fluctuations are reflected by the in-

jections (substorms) of low energy electrons with peak energies of 26 keV (panel 9) at L -values between 5 and 7. These injected particles diffuse radially inward and lead to a symmetric ring current. An intensification of the ring current is also observed in the 212.5 keV electron channel. In the ion channels ring current intensification is seen only for energies up to 85 keV. The 99 keV ion channel (panel 5) indicates no flux intensification which means that the intensity of the quiet ring current is not changing evidently during the ten days period. The maximum of the quiet time ring current is about at $L = 5$, whereas the maximum of the injected particles are further out at $L = 5.5$.

The composition response shows marked differences compared with the storm case. O^+ shows short-lived responses to individual AE events, which occur further out near $L = 6$. He^{++} shows a build up also near $L = 6$, showing solar wind plasma access to the inner magnetosphere during substorms. He^{++} builds up slowly and has a longer lifetime than O^+ , forming a more continuous belt at $L = 6$. The delayed response of He^+ is consistent with the charge-exchange dependence on He^{++} , "outliving" He^{++} by the same delay of about one day.

He^{++} reaches a maximum He^{++}/H^+ energy density ratio levels of 2%, and thus has a negligible effect on Dst . The energy density ratio for O^+/H^+ is 9%, and that for He^+/H^+ 6%. Thus none of the heavier ions are major contributors to substorm related changes in Dst .

Summary

CRRES particle data in a L versus time format allows tracking of the radiation belt particle population during storms and substorms.

During storm the observable effect of substorms seems to be limited to delaying the recovery phase, while the data shows no clear indication of substorm injections down to the main body of the ring current during the storm onset phase. The main body of the ring current moves inwards from its normal position of $L=4.5-5$ and intensifies, which correlated well with the behavior of Dst . Thus our data does not support the Chapman's original hypothesis storm = Σ substorms.

The observed dramatic increase in the O^+/H^+ ratio during storms is also a storm-only effect, as it is not observed for substorms on their own. We have shown that the compositional changes associated with

substorms do not have an effect on Dst and can be ignored.

For substorms the ring current intensification is less and only at lower energies, and occurs further out at L -values between 5 and 7. All these factors explain the moderate effect on Dst . A rough correlation of AE to Dst shows that a series of $AE \sim 800-1000$ nT events leads to a change in Dst of ~ 30 nT. Applying this rough relation to the 9/10 Oct storm, which showed 1400nT AE substorms during the storm main phase, this would lead to a substorm contribution to the minimum Dst observed of ~ 45 nT or 30%. However, this should be detectable by a fairly strong substorm-related increase in the particle populations at higher L , which is not observed.

A possible explanation of this is that the substorm injections during the main phase of a storm occur when the magnetosphere is much distorted, so that injections at higher L do not complete a full drift and never form into a symmetrical ring current, whereas substorm injections do create a symmetrical ring current, which forms further out by about one Earth radius compared to the normal ring current. This result supports the findings of McPherron [1997] who concluded that substorms do not contribute to the storm main phase Dst .

We can thus conclude that while substorms may not play a role in ring-current dynamics during the disturbed storm main phase, repeated substorm activity does form a symmetric ring current at higher L thus contributing to Dst .

The ion composition measurements showed a strong contribution of O^+ during storms. Final storm recovery seems to be more controlled by the recovery of the heavy ions. For substorms ions composition is a minor effect in relation to Dst . However we note here the He^{++} observations which show clear solar wind access to the inner magnetosphere. The delayed response indicates that this is not direct access but rather a result of the front-side reconnection / tail convection scenario.

Acknowledgments We acknowledge the provision of MEA data by Al Vampola, of MICS data by Berend Wilken, and of geometric factors and efficiency parameters by Jim Roeder.
